Why might losses exceed gains?

Symmetry imposed

Asymmetry allowed

The question and the conditional result

1 · Question and result

Can equal institutional changes have unequal output effects?

If a temporary deterioration makes the value of continuing negative and restarting costs more than the restored business is worth, its output loss exceeds the gain from an equal improvement and persists after institutions recover.

Impact asymmetry

Closure creates a discrete output loss.

Persistence

Costly rebuilding prevents recovery.

A conditional firm-level mechanism. It does not identify the thesis's aggregate coefficients.

From economic freedom to two firm-level channels

Economic freedom concerns the ability to use property, make contracts, and exchange. The Economic Freedom of the World (EFW) index measures several institutional dimensions.

Area 1	Area 2	Area 3	Area 4	Area 5
Size of government	Legal system and property rights	Sound money	Freedom to trade internationally	Regulation

s: Institutionally usable property

Share of existing property available for productive use under prevailing institutional conditions. Title disputes or restrictions on property use can make premises unavailable.

Less usable property: $s \downarrow$

EFW's five areas: Fraser Institute

c: Institutional operating overhead

Recurring institutional expenses paid while operating, independently of current output: permit renewals and fixed costs of reporting or customs administration.

Higher operating overhead: $c \uparrow$

From usable property to production

Fixed property		Usable share		Usable property
$\bar{k} > 0$	$\times$	$s \in (0, 1]$	$=$	$s\bar{k}$
The firm's existing stock.		Available under institutions.		Available for production.

1: Combine property with input

Assume Cobb–Douglas production:

$$q = A(s\bar{k})^{1-\alpha} x^{\alpha}.$$

$x \geq 0$: variable input.
$A > 0$: productivity.
$0 < \alpha < 1$: output elasticity of x.

Output price is one: output equals revenue.

2: Choose convenient units

Measure property in units of the firm's fixed stock: $\bar{k} = 1$.

$$\boxed{q = As^{1-\alpha} x^{\alpha}.}$$

$s = 0.5$: half the existing stock is available for production.

An institutional shock changes the usable share s. The physical stock $\bar{k}$ stays fixed.

One experiment, one changed assumption

Baseline: free restarting

$$\kappa = 0$$

Extension: costly restarting

$$\kappa > 0$$

Institutional path	Shock: $t = 0$	Restored: $t \geq 1$
Deterioration	$s_0 - d$	s_0
No change	s_0	s_0
Improvement	$s_0 + d$	s_0

Same firm and known restoration

Initially open; $0 < d < s_0$, $s_0 + d \leq 1$. Restoration is permanent and known at date 0. Hold $c = c_0$ and other parameters fixed.

What closure means

Free closure preserves property but dismantles the organization. No organization-preserving suspension; financing is available. Discount factor: $0 < \beta < 1$.

The complete firm problem

Activity: $a_t \in \{0, 1\}$

1: open. 0: closed. Initially, $a_{-1} = 1$.

Variable input: $x_t \geq 0$

Choose input when open; set $x_t = 0$ when closed.

Choose activity and input to maximize firm value

$$\max_{\{a_t, x_t\}} \sum_{t=0}^{\infty} \beta^t \left[A s_t^{1-\alpha} x_t^{\alpha} - w x_t - (F + c_0) a_t - \kappa a_t (1 - a_{t-1}) \right].$$

Revenue

$$A s_t^{1-\alpha} x_t^{\alpha}$$

$A > 0$ is productivity. Output price is one.

Input bill

$$w x_t$$

Input quantity times its fixed unit price $w > 0$.

Operating overhead

$$(F + c_0) a_t$$

$F > 0$: ordinary fixed cost. $c_0 \geq 0$: institutional overhead. Both paid only when open.

Restart cost

$$\kappa a_t (1 - a_{t-1})$$

Pay $\kappa \geq 0$ only when closed last period and open now. Otherwise, pay zero.

Optimal input and operating profit

2 · Model: solve the continuous choice first

1: Differentiate when operating

$$\alpha A s^{1-\alpha} x^{\alpha-1} = w.$$

The marginal revenue product equals the input price. Strict concavity gives the unique optimum.

2: Rearrange the FOC

$$x^*(s) = s(\alpha A/w)^{1/(1-\alpha)}.$$

3: Substitute and use $wx^* = \alpha q$

$$q(s) = sA(\alpha A/w)^{\alpha/(1-\alpha)},$$

$$\boxed{\pi(s, c_0) = (1-\alpha)q(s) - F - c_0.}$$

Actual output is $y_t = a_t q(s_t)$.

Define $q_0 = q(s_0)$, $\pi_0 = \pi(s_0, c_0)$, and $\pi_\pm = \pi(s_0 \pm d, c_0)$.

The input FOC is unchanged by κ: the restart bill is independent of input, and input does not change tomorrow's state.

Proposition: a temporary setback, a lasting loss

3 · Proposition 1 in the working paper

Maintain the model and matched paths: $A, w, F > 0$, $c_0 \geq 0$, $0 < \alpha, \beta < 1$; initially open, $0 < d < s_0$, $s_0 + d \leq 1$, and known permanent restoration at date one. Financing is available; closure is free, destroys the organization, and has no salvage or suspension option. No entry or reallocation.

Normal viability

$$\pi_0 > 0$$

Normal operation pays.

Continuation loses value

$$\pi_- + \beta V < 0$$

Future profits cannot offset the current loss.

Restart is unprofitable

$$\kappa > V$$

Rebuilding exceeds the restored value.

$$V = \frac{\pi_0}{1 - \beta} > 0.$$

Unique optimal paths: $a_t^- = 0$ and $a_t^0 = a_t^+ = 1$ for every $t \geq 0$.

What changes: persistence, not impact closure

3 · Output comparison and the free-restart baseline

$$L_t = y_t^0 - y_t^-, \qquad G_t = y_t^+ - y_t^0.$$

	Impact loss L_0	Impact gain G_0	Loss after restoration
Costly restart: $\kappa > V$	q_0	$(d/s_0)q_0$	q_0
Free restart: $\kappa = 0$	q_0	$(d/s_0)q_0$	0

In both cases $L_0 > G_0$ because $d < s_0$. After restoration, $G_t = 0$ in both cases.

The same adverse firm closes on impact in both experiments. Free restarting permits recovery at date one.

Proof roadmap: three decisions, one comparison

4 · Proof progress

1. **Input:** strict concavity gives $x^*(s)$, $q(s)$, and $\pi(s, c_0)$.
2. **After restoration:** solve the active and inactive firm's values, including every possible restart date.
3. **At date zero:** compare continuing with closing while retaining the option to reopen.
4. **Output:** apply the chosen activity paths to the linear operating-output function $q(s)$.

The delicate step is the value of closing. Zero is always feasible; it is not always the best value.

Waiting cannot improve the restart value

4 · Lemma 2: all restart dates, including never

1: Active at a restored date

$$V = \pi_0 + \beta\pi_0 + \cdots = \frac{\pi_0}{1-\beta}.$$

Closing would forgo positive profits and could add another restart bill.

2: Closed at a restored date

Restart after $n \geq 0$ periods, then stay open:

$$\beta^n(V - \kappa).$$

Never restart: value zero.

3: Compare every delay

$V > \kappa$: discounting reduces a positive payoff; restart immediately.

$V < \kappa$: every finite delay has a negative payoff; never restart.

$V = \kappa$: all restart dates and never restarting tie.

$$\boxed{W = \max\{V - \kappa, 0\}.}$$

Once restarted, further closures cannot help because $\pi_0 > 0$ and $\kappa \geq 0$. This covers repeated switching too.

Closure retains an option to reopen

4 · Compare values at the same date

Keep operating at date zero

$$\pi_j + \beta V$$

Current profit plus restored business value.

Close at date zero

$$\beta \max\{V - \kappa, 0\}$$

Zero current payoff plus the option to restart.

Under the proposition's strict conditions

$\kappa > V$ makes closing worth zero. Adverse continuation is negative, so closure is optimal. Normal continuation is $V > 0$; favorable continuation is even larger.

With $\kappa = 0$, closure is worth βV. Since $\pi_- < 0$, the adverse firm still closes, but reopens at date one.

a_t is binary: its optimality condition is a value comparison, not a derivative with respect to activity.

The conditions can hold together

4 · Nonempty parameter region

$A = 2$, $\alpha = 0.5$, $w = 1.25$, $F = 0.30$, $c_0 = 0.09$, $s_0 = 0.50$, $d = 0.20$, $\beta = 0.90$, $\kappa = 0.40$.

Compute from the primitives

$$q_0 = 0.80, \quad \pi_0 = 0.01, \quad V = 0.10,$$
$$\pi_- = -0.15, \qquad \pi_+ = 0.17.$$

Check the strict inequalities

$$\pi_- + \beta V = -0.06 < 0, \qquad \kappa > V.$$

Why a thin margin matters

Permanent closure requires

$$\frac{\pi_0}{(1-\alpha)q_0} < (1-\beta)\frac{d}{s_0}.$$

Here $0.025 < 0.04$. Normal operation is profitable, but future earnings are small relative to the shock loss.

All inequalities are strict: a neighborhood of this example also satisfies the proposition. The result is not universal.

Proof status: done, difficult, open

4 · Analytic proofs versus remaining research

Proved in the paper

Unique input optimum.

All delayed restart values.

Strict persistence and the complete closure threshold.

Cheap-suspension threshold.

The difficult step

Accounting for closure's option value.

Ruling out arbitrary delay and repeated switching.

Separating impact from recovery.

Still open

Entry and reallocation.

A heterogeneous-firm equilibrium.

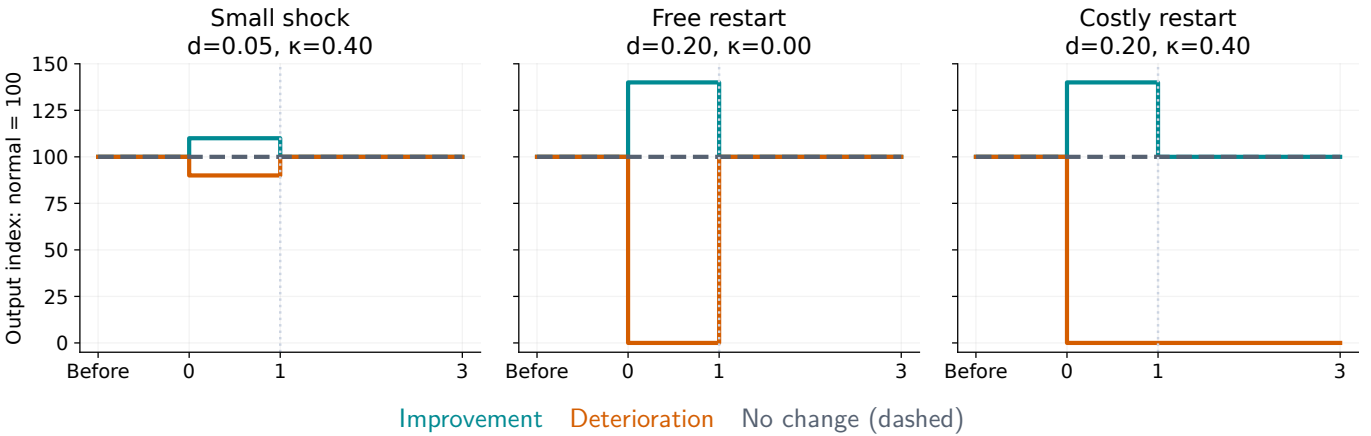

Empirical measurement of restart and preservation costs.

Independent assessment of the remaining AI contributions.

Analytic completion, numerical checks, Lean coverage, and independent author review are separate claims.

Three reproduced cases: same model

5 · Numerical illustrations, not calibration

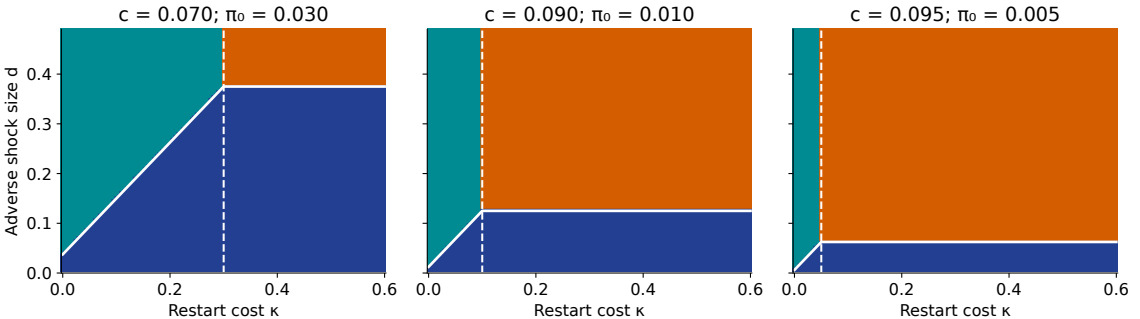

Small shocks: keep operating. Large shocks: close. Restart costs distinguish recovery from permanent inactivity.

Where does each operating regime occur?

5 · Proposition 2 and parameter comparisons

Strict closure if

$$(1-\alpha)q_0\frac{d}{s_0} > \pi_0 + \beta\min\{\kappa, V\}.$$

Higher κ can discourage closure today; higher c_0 lowers normal margins and expands the permanent-closure region. White curves mark closure indifference; dashed lines mark $\kappa = V$.

Explore the decision margins

5 · Interactive companion: shock, restart cost, and overhead

Experiment	d	κ	c_0	Adverse-firm path
Small shock	.05	.40	.09	Keep operating
Free restart	.20	0	.09	Close, then reopen
Costly restart	.20	.40	.09	Close permanently
Stronger normal margin	.20	.40	.07	Keep operating
Avoid a costly restart	.10	.40	.09	Keep operating

What to vary live

First compare the three topic cases. Then lower c_0, holding the shock fixed. Finally hold $d = 0.10$ and compare $\kappa = 0$ with $\kappa = 0.40$.

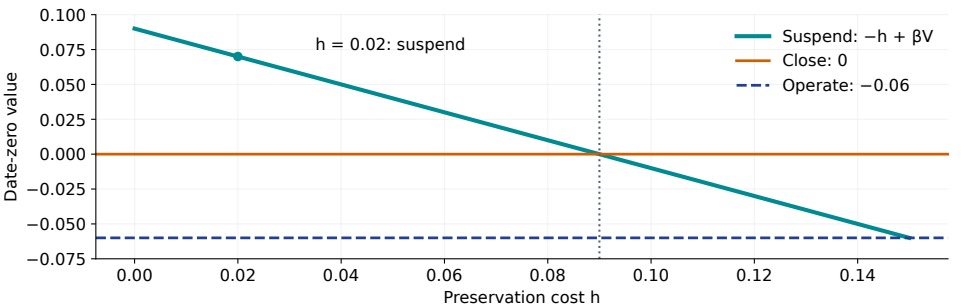

The interactive version updates both values and output paths. It keeps c_0 constant over time within each experiment.

First robustness test: cheap suspension

5 · Proposition 3: preserve the organization for a cost h

At date zero, suspension produces nothing, costs $h \geq 0$ in total, and preserves the organization for free resumption at date one. It replaces operating overhead for that period.

Suspend: $-h + \beta V$; close: 0; operate: $\pi_- + \beta V < 0$.

If $h < \beta V$, suspension strictly wins. Impact loss remains, but production fully recovers at date one. At $h = \beta V$, suspension and closure tie.

What the calculations check and leave open

5 · Scope of the numerical evidence

Checked

Symbolic FOC and numerical input optimum.

Three topic cases reproduced.

168 parameter points: compare closed-form decisions with all five-date activity sequences and an exact stationary tail.

151 suspension costs; delay, tie, and browser/Python checks.

Not established by those checks

A finite grid is not a proof over all parameters.

No estimated EFW shock or calibrated GDP effect.

Entry and heterogeneity remain open: $\kappa > V$ does not exclude favorable date-zero entry.

Fixed-cohort totals are accounting, not general equilibrium.

Even when $\kappa > V$, an otherwise identical inactive owner can enter during the improvement if $\pi_+ + \beta V - \kappa > 0$. Entry and reallocation can alter the aggregate comparison.

Lean checks every possible restart path

Paper: Lemma 2, costly-restart clause

Under A1–A6, "permanent inactivity is uniquely optimal if $V < \kappa$."

$$V = \frac{\pi_0}{1-\beta}, \qquad \pi_0 > 0, \quad 0 < \beta < 1.$$

Read the formal statement

`pi` is π_0; `false` means initially closed.

`a` is any infinite sequence of activity choices.

The maximum is zero. Only the never-restart path attains it.

Actual Lean statement

```
lemma restored_inactive_optimal_iff_inactive {pi beta kappa : ℝ}
    (hpi : 0 < pi) (hbeta0 : 0 < beta) (hbeta1 : beta < 1)
    (hkappa : 0 ≤ kappa) (hkgt : pi / (1 - beta) < kappa)
    (a : ActivityPath) :
    restoredPathValue pi beta kappa false a =
      max (pi / (1 - beta) - kappa) 0 ↔ a = alwaysInactive := by
```

Proof excerpt: equality forces the inactive path

```
  rw [restoredPathValue_eq_potential_iff_slack_zero
    hpi hbeta0 hbeta1 hkappa]
  constructor
  · exact tight_inactive_forces_inactive
      hpi hbeta0 hbeta1 hkappa hkgt a
```

`lean/MainTheorems.lean`; statement line breaks adapted.

The proof bounds the infinite discounted payoff of every path. Equality requires no profitable decision to be forgone at any date; here that forces permanent inactivity.

Lean: verified scope and the remaining gap

6 · Compiling a proof and checking its economic meaning are different tasks

What has compiled

Six formal counterparts of the paper's numbered results, with no `sorry`.

The input optimum and the reduced activity problem, including arbitrary infinite paths.

Switching thresholds, suspension comparisons, and positive-total log comparisons.

What remains open

The formal bridge from joint input/activity maximization to the reduced activity problem.

This includes unoptimized plans whose discounted losses are infinite.

The required fast check passed. Full source-correspondence certification remains incomplete.

Paper version: merged commit `a15ed978`. Complete declarations and command records accompany the paper.

Lean checks the specified input and reduced dynamic problems. I do not yet claim verification of the full original optimization problem.

The AI-assisted step I checked by hand

7 · Selected derivation: closure with an option to reopen

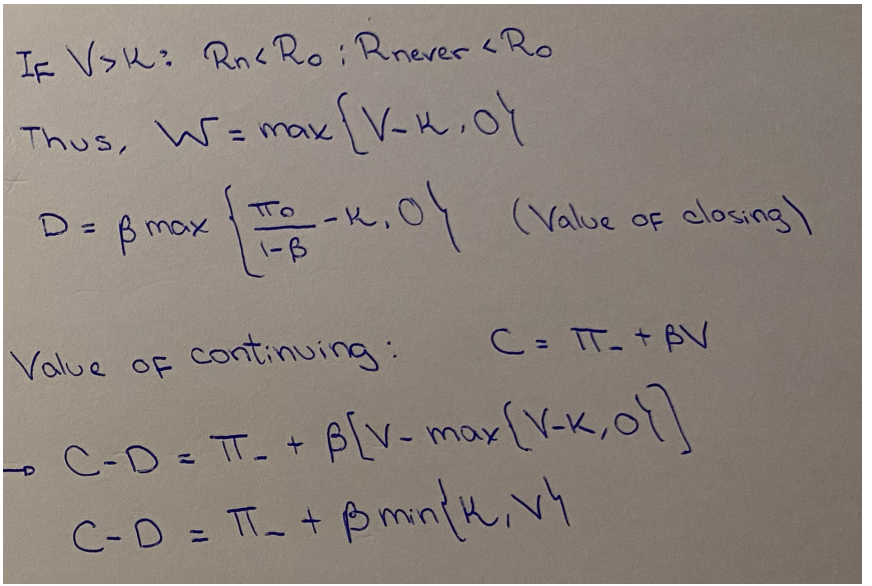

1. At date one, immediate restarting yields $V - \kappa$.
2. Restarting n periods later yields $\beta^n(V - \kappa)$.
3. Include never restarting, with value zero.
4. Compare positive, zero, and negative $V - \kappa$; discount the best value once to date zero.

$$\boxed{\text{Closing value at date zero} = \beta \max\{V - \kappa, 0\}.}$$

An AI-generated uniqueness helper allowed $\beta = 0$: then future actions do not affect value. The paper already requires $\beta > 0$. That diagnostic is separate from my handwritten closure-value check.

My handwritten check and assessment

7 · My revision · November 9, 2026

My verdict

"I accept it."

My restart calculation

$$R_n = \beta^n (V - \kappa), \qquad n \geq 0,$$

$$R_{\text{never}} = 0.$$

Compare delayed reopening with never reopening, then discount once to date zero.

Enlarged excerpt of my original photograph. The complete page is in backup slide 29.

Three questions for class discussion

8 · Discussion: 15 minutes

1. **Suspension:** what observable evidence would distinguish temporary shutdown from organization-destroying closure? Which costs should h include?

2. **Aggregation:** what is the smallest model of heterogeneous firms, entry, and reallocation that could preserve the loss–gain comparison?

3. **Timing and margins:** should the next extension vary the duration of restoration or relax perfect foresight? How would we identify the fragile firms?

github.com/gsaco/ai-project: working paper, code and check logs, Lean artifacts, and AI record. The October topic submission is preserved.

I use an established sunk-cost mechanism in a deterministic institutional experiment. The contribution is the precise conditional comparison and its limits.

Continuation minus closure value

$$\pi_- + \beta V - \beta \max\{V - \kappa, 0\} = \pi_0 - (1-\alpha) q_0 \frac{d}{s_0} + \beta \min\{\kappa, V\}.$$

A negative difference implies closure; a positive one implies operation; zero gives indifference.

After closure: $\kappa < V$ implies immediate restart; $\kappa > V$ implies never restarting; $\kappa = V$ allows any restart date or none.

Under every optimal selection, $L_t \geq G_t \geq 0$. Strictness occurs at impact exactly when the adverse firm closes; later exactly when it remains closed.

The numerical convention keeps operating at a closure tie and declines a zero-value restart. The strict proposition does not depend on that convention.

A fixed-cohort accounting extension

$$Y_t^j = B + N y_t^j, \qquad B > 0, \quad N > 0.$$

Under Proposition 1, strict level asymmetry implies

$$2Y_t^0 > Y_t^- + Y_t^+ \geq 2\sqrt{Y_t^- Y_t^+},$$

$$(Y_t^0)^2 > Y_t^- Y_t^+ \quad \Longrightarrow \quad \log Y_t^0 - \log Y_t^- > \log Y_t^+ - \log Y_t^0.$$

Common population cancels from per-capita log differences. A closed firm's log output is undefined. Even symmetric level changes can be asymmetric in logs.

This is not a model of GDP: it holds background output and the cohort fixed and omits entry, prices, and reallocation.

Backup: my original handwritten revision
